Case Report

Seventeen days old female baby was presented with 4 cm x 4 cm and 3 cm x 4 cm in size lumps on the dorsum of tongue and palate. Both lesions were pink in color and soft in consistency. Palatal lesion arose through the palatal cleft was covered with fair amount of hair strands figure 1. MRI scan had been performed and revealed that the lumps were localized and not extended to adjacent structures. Patient had experienced difficulty in breathing and feeding. Excessive salivation was also present. Surgical excision had been performed under general anesthesia and specimens were sent for histopathological investigation.

Microscopic finding of palatal lump revealed a polypoid mass covered by the epidermis. The dermis contained hair follicles, sweat and sebaceous glands figure 2.
The corium was composed of dense collagen fiber bundles. The deeper area contained mature adipose tissue. The sections taken from the separate soft tissue showed mucosa covered by a combination of orthokeratinized stratified squamous epithelium, parakeratinized stratified squamous epithelium and respiratory epithelium. The corium was composed of loosely arranged fibrous tissue and showed increased vascularity. Immunohistochemical stain for Glial Fibrillary Acidic Protein (GFAP) was negative. The lesion was diagnosed as a hairy polyp.

The sections taken from the tongue mass showed a mucosal nodule covered by orthokeratinized stratified squamous epithelium. The corium is composed of skeletal muscles, minor salivary tissues, adipose tissue and cartilage figures 3A,B. Several keratin filled cysts were also observed figure 3C. The lesion was diagnosed as choristoma.

DISCUSSION

Hairy polyp is a rare benign lesion of the oral cavity derived from ectoderm and mesoderm. It predominantly occurs in the oronasopharynx and presents as pear shaped or sausage shaped pedunculated or sessile mass. Hairy polyp frequently presents as an isolated defect. Soft and hard palate clefts, ankyloglossia, agenesis of uvula and external auricle, facial hemi hypertrophy, left carotid artery atresia and
osteopectrosis are rare anomalies associated with hairy polyp. Clinical presentation depends on size, site and shape of the lesion. Feeding difficulties, vomiting, intermittent mild respiratory problems, asphyxia, hemoptysis, unilateral drainage and protruding mass are some of the associated clinical features [7].

Malignant transformation of hairy polyp has not been reported. The incident of hairy polyp is 1: 40,000 live births and shows female predilection with a ratio of 6:1. There is no evidence of familial tendency [3,8].

The origin of hairy polyp is hugely debated and several theories have been developed. The theory suggests that the hairy polyp originates from disturbed development of stomodeum during 28th week of intrauterine life.

Macroscopically the hairy polyp ranges from 0.5 cm to 6 cm in size and pink coloured pear or sausage shaped mass [2]. It is covered by epidermis and associated skin appendages originated from ectoderm and may also consists of fibro fatty tissue accompanied by striated muscles, cartilage, blood vessels, nerves, lymphoid follicles, mucous and serious glands, from mesoderm. Similar to the literature, diameter of palatal lump of the present case was 3cm and was pink in colour. It was covered by epidermis and contained hair strands.

The diagnosis can be arrived with physical examination and confirmed by histology. Radiological examination plays a major role in localizing the origin and extension of the lesion. CT and MRI are also helpful in diagnosing hairy polyp [5,9]. Surgical excision is the treatment of choice and no recurrences have been reported after complete excision. In the present case MRI was used to investigate the extension of the lesion and was confirmed histologically after excision as a hairy polyp.

Choristoma is defined as a tumor like mass of normal cells or tissues that are presented in abnormal locations. It can be in the skin or in the oral cavity mucosa. It is an extremely rare condition. Choristoma was originally reported by Monserrat in 1913 [10]. It is a benign lesion frequently affecting the dorsum of the tongue posterior to the circumvallate papillae and less frequently in other sites of oral cavity including buccal

mucosa, soft palate and gingiva [6,9,10]. Choristoma presents as an asymptomatic pedunculated or sessile lump. Depending on the site, occasionally pain, dysphagia, gagging sensation, throat irritation, nausea and vomiting can be experienced. It shows female predilection with a ratio of 4:1. The size can be varied from 0.3 cm to 2.5 cm. Choristoma can be observed mainly during second to fourth decade of life and age ranges from 8 to 73 years [11]. The present case also showed dysphagia as it covered whole mouth and is a female baby.

The exact origin of Choristoma remains unknown and some lesions present as a developmental malformation whereas others may be of reactive origin due to trauma or chronic irritation [12,13]. It shows clinical behavior of benign lesion and recurrences or malignant transformations have not been reported.

Definitive diagnosis of the Choristoma is performed by histological examination. It may consist of proliferation of bone (frequently seen), cartilage, fat, neural and glial tissues, thyroid gland, respiratory, gastric or intestinal mucosa. The histopathology of Choristoma reveals the presence of mature lamellar bone together with well-developed haversian system and bone marrow spaces. A well-developed mass of viable cartilage or mixture of bone and cartilage surrounded by dense fibrous connective tissues has also been observed. Osteoblastic or osteoclastic activity is a rare presentation. The present case also contained cartilage tissue and fatty tissue.

Differential diagnosis of intraoral choristoma depends on the site of the lesion. When it presents near the foramen caecum of tongue, the differential diagnosis could be a lingual thyroid. When it presents on anterior and lateral aspects of the tongue, the differential diagnosis could be benign tumour including granular cell tumor. Salivary gland neoplasms, mucous retention cyst and lipoma shall be included in the differential diagnosis when it presents on ventral surface of the tongue. The treatment of choice is a simple surgical excision of the lesion and follow up is indicated.
